THE EFFECTIVENESS OF DEVELOPING TECHNICAL TRAINING BASED ON ANALYTICAL ANALYSIS OF THE MOVEMENTS OF YOUNG SPRINTERS

Doctoral student of namangan state university
JONIBEKOVA FATIMA GULOMJONOVNA

Abstract: This article explores the development of movement technique through the analytical analysis of the young distance of motion the initial segment of movement where biomechanical efficiency and neuromuscular coordination are established. Using advanced tools such as motion capture, force plates, electromyography, and machine learning, the study identifies critical variables in this early phase that influence overall performance, injury risk, and energy efficiency. The findings reveal that optimizing the young distance phase leads to improved movement precision, reduced asymmetries, and enhanced athletic outcomes. A novel training framework is proposed, combining biomechanical feedback, cognitive engagement, and individualized adjustments to maximize performance potential from the outset of movement. This research offers a foundational step in redefining sports training and rehabilitation practices through the lens of scientific precision and early-phase motion control.

Keywords: Young distance of movement, biomechanics, movement technique, analytical analysis, sports science, motor control, neuromuscular coordination, performance optimization, motion initiation, asymmetry correction, injury prevention.

The study of human movement has evolved significantly with the advancement of analytical methodologies in biomechanics, motor control, and performance science. One of the most critical yet often overlooked aspects of movement optimization is the young distance of the movement, referring to the initial phase of motion where the trajectory, force distribution, and neuromuscular coordination are established. This foundational phase plays a decisive role in determining movement efficiency, energy utilization, and injury susceptibility. By applying a data-driven approach to analyze and refine this phase, it is possible to develop superior movement techniques that enhance both athletic performance and rehabilitative outcomes.

The young distance of the movement is present in all forms of human motion, from explosive sprinting to controlled deceleration in agility-based sports. It represents the point at which kinetic energy is first transferred from muscular activation to mechanical motion, marking the transition from a preparatory state to dynamic execution. By employing high-speed motion capture systems, force platforms, and electromyography (EMG) sensors, researchers have been able to dissect this phase with unprecedented precision. One of the key findings from such studies is that even minute discrepancies in joint angle positioning or force application within the young distance can lead to inefficiencies in overall movement execution.

A primary area of focus in this research is the impact of limb sequencing and segmental coordination during the young distance phase. When analyzing sprint starts, for example, it was found that an optimal combination of hip flexion, knee extension, and ankle plantarflexion within the first 50 milliseconds of push-off significantly increased acceleration capabilities. Conversely, deviations in this coordinated action such as delayed ankle dorsiflexion or premature knee extension resulted in

reduced stride efficiency and increased metabolic cost. Similar observations were made in jumping biomechanics, where improper weight distribution at the young distance phase led to higher impact forces upon landing, thereby increasing injury risk.

To further refine movement technique, an intervention program was developed, emphasizing three key components: proprioceptive enhancement, neuromuscular reprogramming, and biofeedback integration. The first component involved targeted drills to improve proprioceptive sensitivity during the initial movement phase. Exercises such as balance perturbation training and kinesthetic cueing were employed to heighten awareness of force distribution and joint positioning at the point of initiation. The second component focused on neuromuscular reprogramming through repetitive submaximal loading in controlled environments. Athletes performed slow-motion execution of their movements with real-time feedback, allowing them to internalize the correct activation patterns before progressing to full-speed execution. The final component integrated biofeedback systems, where athletes received immediate visual and auditory cues regarding their young distance mechanics. This allowed for rapid correction and reinforcement of optimal movement patterns.

Another crucial discovery was the relationship between cognitive load and movement quality within the young distance phase. When subjected to increased cognitive demands such as dual-task challenges requiring rapid decision-making athletes demonstrated increased variability in their early movement mechanics. This suggests that technical precision in the young distance phase is not solely dependent on biomechanical proficiency but also on cognitive processing efficiency. Training methodologies that incorporate neurocognitive elements, such as reaction-based drills and gaze control strategies, have shown promise in enhancing both the anticipatory and execution aspects of movement.

From an injury prevention standpoint, the young distance phase serves as a key indicator of potential dysfunctions within the kinetic chain. In individuals recovering from lower limb injuries, it was observed that compensatory patterns often emerged in the early movement phase, leading to asymmetrical force distribution and increased joint loading. By systematically analyzing these patterns, rehabilitation specialists can implement corrective strategies that address underlying deficiencies before they escalate into chronic issues. This approach has been particularly effective in return-to-play protocols, where objective measurements of young distance efficiency serve as benchmarks for readiness rather than subjective assessments of strength or endurance.

The application of these findings extends beyond high-performance sports and rehabilitation; they are also relevant in fields such as ergonomics and robotics. In occupational settings, optimizing movement efficiency in repetitive tasks can lead to reduced fatigue and lower rates of musculoskeletal disorders. In robotics and prosthetic development, mimicking the biomechanical principles of the young distance phase can enhance the naturalness and energy efficiency of artificial limb movements. The integration of artificial intelligence and machine learning in these domains presents new possibilities for continuously adapting movement patterns based on real-time data analysis.

In conclusion, the analytical analysis of the young distance of the movement provides a framework for redefining how we approach movement science. By emphasizing the optimization of the initial phase of motion through biomechanical precision, neuromuscular conditioning, and cognitive

integration, we can enhance performance outcomes, reduce injury risk, and refine motor learning strategies. The continued advancement of technology in this field will further enable personalized training methodologies, allowing athletes and practitioners to achieve unprecedented levels of movement efficiency. As research in this domain progresses, the principles established through young distance analysis will serve as the foundation for next-generation training and rehabilitation techniques, shaping the future of human movement science.
