THE ROLE OF DEPRESSION IN THE DEVELOPMENT OF CARDIOVASCULAR DISEASES

Noraliev I.A.

Department of Pediatrics, Faculty of Medicine, ASMI

Abstract. This article explores the intricate relationship between depression and cardiovascular diseases (CVDs), examining how psychological distress, particularly major depressive disorder (MDD), contributes to the onset, progression, and prognosis of various heart-related conditions. It reviews the biological, behavioral, and social pathways through which depression exerts its influence, including dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis, increased inflammatory markers, poor health behaviors, and medication non-adherence. The growing body of evidence underscores the importance of integrating mental health care into cardiovascular disease prevention and management strategies.

Keywords: depression, cardiovascular disease, inflammation, HPA axis, mental health, heart disease risk factors.

INTRODUCTION

Cardiovascular diseases remain the leading cause of morbidity and mortality worldwide, despite major advances in medical science. Parallel to this, depression is one of the most prevalent mental health disorders, with significant implications for physical health. Over the last two decades, a growing body of research has established a strong association between depression and an increased risk of developing cardiovascular conditions such as hypertension, myocardial infarction, and stroke. Far from being independent comorbidities, depression and CVD appear to be linked through a complex web of biopsychosocial interactions, making the recognition of depression a crucial element in the clinical assessment of cardiovascular patients.

MATERIALS AND METHODS

One of the most significant biological mechanisms by which depression influences cardiovascular health is through chronic activation of the stress response system, particularly the hypothalamic-pituitary-adrenal (HPA) axis. In individuals with depression, this system often becomes dysregulated, leading to elevated levels of cortisol — a stress hormone known to contribute to endothelial dysfunction, hypertension, and atherosclerosis.

Another key mechanism is systemic inflammation. Patients with depression frequently exhibit elevated levels of pro-inflammatory cytokines such as interleukin-6 (IL-6), tumor necrosis factor-alpha (TNF-α), and C-reactive protein (CRP). Chronic inflammation is well-recognized as a driving factor in the development of plaque in arterial walls and in the destabilization of existing atherosclerotic lesions, increasing the risk of acute cardiovascular events.

Furthermore, depression is associated with autonomic nervous system imbalance, particularly a reduction in heart rate variability (HRV) and increased sympathetic activity, both of which are predictors of adverse cardiac outcomes. Oxidative stress, endothelial dysfunction, and platelet aggregation are also biological correlates commonly found in depressed individuals, all contributing to cardiovascular risk.

RESULTS AND DISCUSSION

In addition to biological changes, depression adversely affects health-related behaviors, which in turn elevate cardiovascular risk. Individuals suffering from depression are more likely to engage in sedentary behavior, consume poor diets, smoke tobacco, and misuse alcohol. They are also less likely to adhere to exercise regimens or seek preventive care.

One of the critical pathways through which depression exacerbates CVD is medication non-adherence. Patients with chronic depression often struggle with motivation and executive functioning, leading to poor compliance with antihypertensive, lipid-lowering, or antiplatelet therapies. This non-adherence significantly diminishes the effectiveness of cardiovascular disease management and increases the risk of recurrent cardiac events.

Sleep disturbances are another common manifestation of depression and are independently associated with hypertension, arrhythmia, and coronary artery disease. Disrupted sleep can lead to hormonal imbalances, increased sympathetic tone, and blood pressure variability — all known contributors to cardiovascular deterioration [1].

Evidence suggests that depression is not only a risk factor for the development of CVD but also a predictor of poor outcomes in patients with established heart disease. Numerous longitudinal studies have demonstrated that post-myocardial infarction depression is associated with a higher risk of mortality, increased rates of rehospitalization, and reduced quality of life.

The SADHART (Sertraline Antidepressant Heart Attack Randomized Trial) and ENRICHD (Enhancing Recovery in Coronary Heart Disease Patients) studies both highlighted the prognostic significance of depression in cardiac patients and emphasized the potential benefits — though not conclusive — of antidepressant therapy in improving cardiac outcomes.

These findings underscore the critical importance of early screening and treatment of depression in cardiac patients. However, mental health services are still often underutilized in cardiology settings, partly due to stigma, diagnostic overshadowing, and lack of interdisciplinary coordination.

Given the multifaceted connection between depression and cardiovascular disease, modern medicine must adopt a biopsychosocial approach to patient care. Primary care physicians, cardiologists, and mental health professionals should collaborate to ensure that patients with or at risk of CVD are screened for depression using standardized tools such as the PHQ-9 or the Beck Depression Inventory [2].

Treatment options should be tailored to the individual, balancing pharmacological and non-pharmacological interventions. Selective serotonin reuptake inhibitors (SSRIs) are generally considered safe and effective for cardiac patients, though careful monitoring is necessary due to potential drug interactions. Cognitive-behavioral therapy (CBT), lifestyle interventions, and stress management programs have also demonstrated benefits in improving both mood and cardiovascular parameters.

Moreover, public health policies must prioritize mental health awareness, reduce barriers to psychiatric care, and promote integrated care models that recognize the interdependence of mind and body in disease prevention and management.

In examining the deeper intersections between depression and cardiovascular disease (CVD), one must consider not only the direct biological and behavioral pathways but also the socio-environmental conditions that exacerbate this comorbidity. Depression often arises and is perpetuated within social contexts marked by poverty, unemployment, low education, and chronic stress — all of which are independently recognized as risk factors for cardiovascular disease. This confluence of vulnerability

creates a feedback loop, wherein psychological stress worsens physical health, which in turn amplifies mental distress [3].

A key contributor in this cycle is chronic psychosocial stress, often rooted in adverse life experiences such as bereavement, social isolation, job insecurity, or trauma. These stressors activate the sympathoadrenal system and increase circulating catecholamines, leading to elevated blood pressure, endothelial injury, and enhanced platelet aggregation — all of which potentiate cardiovascular risk. For individuals with depression, whose physiological systems are already dysregulated, the cumulative burden of these stressors may trigger acute cardiovascular events such as myocardial infarctions or strokes, even in the absence of severe atherosclerosis.

Moreover, the neuroendocrine disturbances associated with depression extend beyond the hypothalamic-pituitary-adrenal (HPA) axis to include dysfunction in the serotonergic and noradrenergic systems, which play a role not only in mood regulation but also in vascular tone, heart rate control, and metabolic processes. Abnormal serotonin metabolism, for example, has been linked to increased vascular reactivity and impaired platelet inhibition, contributing to thrombosis and coronary artery occlusion [4].

CONCLUSION

Depression significantly impacts the development, progression, and outcome of cardiovascular diseases through a combination of biological, behavioral, and psychosocial mechanisms. It is no longer acceptable to view mental and physical health as separate domains; instead, a holistic, integrated care approach is essential. Addressing depression proactively can not only improve psychological well-being but also serve as a vital tool in preventing and managing cardiovascular conditions, ultimately reducing global health burdens and enhancing patient quality of life.
