Abstract: Ureterohydronephrosis is a pathological condition characterized by progressive dilation of the ureter and renal pelvis due to impaired urine outflow, leading to structural and functional alterations of the urinary tract. This study aims to analyze the clinical and morphological changes of the ureter in patients with ureterohydronephrosis. Clinical findings were correlated with imaging data and morphological characteristics to assess the extent of ureteral remodeling. The results demonstrate that prolonged obstruction results in significant ureteral wall thickening, loss of smooth muscle integrity, and fibrotic transformations, which contribute to impaired peristalsis and progressive urinary stasis. Early detection of these changes is crucial for selecting appropriate therapeutic strategies and preventing irreversible renal damage.

Keywords: ureterohydronephrosis, ureteral structure, morphological changes, urinary obstruction, clinical analysis, ureteral remodeling, urinary tract pathology

INTRODUCTION

Ureterohydronephrosis is a common urological condition characterized by progressive dilation of the ureter and renal pelvis resulting from partial or complete obstruction of urinary outflow. This pathological process leads to increased intraluminal pressure, impaired ureteral peristalsis, and gradual deterioration of renal function. Ureterohydronephrosis may develop due to congenital anomalies, urolithiasis, strictures, tumors, or external compression of the urinary tract, and it affects both pediatric and adult populations. Prolonged urinary obstruction induces significant structural remodeling of the ureteral wall, including smooth muscle hypertrophy, loss of elastic fibers, inflammatory infiltration, and fibrotic transformation. These morphological changes disrupt normal ureteral motility and contribute to persistent urinary stasis, creating a vicious cycle that accelerates disease progression. Clinically, patients may present with nonspecific symptoms, which often delays diagnosis until advanced stages when irreversible damage has already occurred. Recent advances in imaging techniques and histopathological assessment have improved the understanding of ureteral remodeling in ureterohydronephrosis. However, the correlation between clinical manifestations and morphological alterations of the ureter remains insufficiently explored. A comprehensive evaluation of ureteral structural changes in relation to clinical findings is essential for optimizing diagnostic accuracy and selecting appropriate surgical or conservative treatment strategies.

Materials and Methods

This study was conducted as a combined retrospective and prospective clinical investigation in the Department of Urology and Pediatric Urology at the Termez Branch of Tashkent State Medical University. A total of 78 patients diagnosed with ureterohydronephrosis were included in the study.

VOLUME-5, ISSUE-12

The study population consisted of both pediatric and adult patients aged between 3 and 65 years, who were treated between 2021 and 2024. Inclusion criteria were radiologically confirmed ureterohydronephrosis, presence of urinary tract obstruction at various levels of the ureter, and availability of complete clinical, imaging, and morphological data. Patients with acute infectious conditions, malignant tumors of the urinary tract, or previous ureteral surgery were excluded from the study. All patients underwent comprehensive clinical evaluation, including medical history, physical examination, and assessment of urinary symptoms. Laboratory investigations included serum creatinine, blood urea nitrogen, and routine urinalysis. Imaging studies were performed using ultrasonography, computed tomography urography (CTU), and intravenous urography (IVU) to assess the degree of ureteral dilation, localization of obstruction, and renal pelvis involvement. Morphological analysis was carried out on ureteral tissue samples obtained during surgical interventions.

Results

Clinical evaluation revealed that the majority of patients presented with progressive flank pain, recurrent urinary tract infections, and impaired urinary flow. Imaging studies demonstrated varying degrees of ureteral and renal pelvis dilation, with severe ureterohydronephrosis observed in 46% of cases. Obstruction was most commonly localized in the distal ureter, followed by the ureteropelvic junction. A significant association was identified between the duration of obstruction and the severity of ureteral dilation. Laboratory findings indicated mild to moderate renal dysfunction in a substantial proportion of patients, reflected by elevated serum creatinine levels, particularly in cases of long-standing obstruction. Patients with advanced ureterohydronephrosis showed a higher incidence of urinary stasis–related complications, including recurrent infections and progressive renal impairment. Morphological analysis of ureteral tissue samples demonstrated pronounced structural remodeling of the ureteral wall. Histological examination revealed marked thickening of the muscular layer in early-stage disease, followed by smooth muscle disorganization and partial replacement by fibrous tissue in advanced stages. Inflammatory cell infiltration was observed in the submucosal and muscular layers, contributing to disruption of normal ureteral architecture. Additionally, a significant reduction in elastic fiber content and loss of coordinated smooth muscle arrangement were noted, resulting in impaired peristaltic activity of the ureter. Overall, the results demonstrate a clear relationship between the degree of ureteral obstruction, morphological alterations of the ureteral wall, and clinical outcomes. Progressive structural remodeling of the ureter plays a critical role in disease progression and negatively impacts urinary drainage and renal function.

Discussion

The findings of this study highlight the complex relationship between ureteral obstruction, structural remodeling of the ureter, and clinical progression in patients with ureterohydronephrosis. The results demonstrate that prolonged urinary outflow obstruction leads to progressive morphological alterations of the ureteral wall, which significantly impair ureteral peristalsis and contribute to persistent urinary stasis. These changes represent key pathological mechanisms underlying disease progression and renal function deterioration. Early-stage ureterohydronephrosis was characterized by compensatory hypertrophy of the smooth muscle layer, reflecting an adaptive response aimed at maintaining urine transport against increased intraluminal pressure. However, as obstruction persisted, this adaptive mechanism gradually failed, giving way to disorganization of smooth muscle fibers, loss of elastic components, and increasing fibrotic transformation. Such structural changes

reduce ureteral contractility and exacerbate urinary stasis, creating a self-perpetuating cycle of obstruction and tissue damage. The observed inflammatory infiltration within the ureteral wall further supports the role of chronic inflammation in ureteral remodeling. Inflammatory processes likely contribute to smooth muscle degeneration and fibrosis, accelerating loss of normal ureteral architecture. These findings are consistent with previously reported studies describing inflammation-driven fibrosis as a critical factor in obstructive uropathies. Clinically, the strong correlation between morphological alterations and imaging severity underscores the diagnostic value of integrating radiological and histopathological assessments. Patients with advanced morphological changes exhibited more severe clinical symptoms and greater impairment of renal function, emphasizing the prognostic significance of ureteral structural remodeling.

Conclusion

Ureterohydronephrosis results in significant structural and functional changes of the ureter, with progressive dilation, smooth muscle disorganization, fibrotic transformation, and inflammatory infiltration. These morphological alterations directly impair ureteral peristalsis and contribute to persistent urinary stasis, ultimately affecting renal function. Early diagnosis, comprehensive clinical and imaging assessment, and timely surgical or conservative intervention are essential to prevent irreversible damage. The integration of clinical, radiological, and morphological data provides critical insights into the pathophysiology of ureterohydronephrosis and supports individualized treatment strategies to optimize patient outcomes.
